Acknowledgements

I want to thank my advisor, Dr. Ou Bai, for providing me with the opportunity to work on a subject that I enjoy, and for his good humor even when I made stupid PCB layout mistakes that rendered a batch of boards mostly useless (and I only wish that had just happened once). Thank you for being the jolliest advisor I could possibly have. I also want to thank Dr. Fei for providing the equipment and workspace for all my soldering needs.

I also thank my parents, Charles Kelly and Logan Smith, for their love and support, and for letting me mooch off of them for 24 years and counting. Without their continuous input of effort and generosity, I would be either homeless and uneducated, or dead (probably both). Thanks also to my brother, Jared Kelly, for his invaluably entertaining company in the times I just wanted to hang out and completely forget about "doing science."

I would like to thank my friends and lab-mates (and former lab-mates) Tyler Ferro, Chris Hagerty-Hoff, Plamen Nikolov, Jay Freitas, Natalie Vazquez, and Tareq al-Shargabi, for their company and their valuable input. Thanks also to my girlfriend, Marissa Shaffer, for her encouragement and for keeping me on track.

Finally, I would like to thank Charles Taylor, for his willingness to take me under his wing way back in my just-finished-undergrad days, and for teaching me so much about the practicalities of engineering. If it weren't for him, I would never have developed my interest in electronics in the first place, nor would I have been introduced to the vast maker community that encourages me to continue growing that interest. I learned as much about hands-on engineering work during my year-long stay in the Artificial Heart Lab as I had in four years of undergraduate training, and there are no words or estimation for how valuable that time was.

Abstract

DEVELOPMENT OF A COMPACT, LOW-COST WIRELESS DEVICE FOR BIOPOTENTIAL ACQUISITION

By Graham S. Kelly, B.S.

A thesis submitted in partial fulfillment of the requirements for the degree of Master of Science at Virginia Commonwealth University.

Virginia Commonwealth University, 2014.

Major Director: Ou Bai, Ph.D., Assistant Professor, Department of Biomedical Engineering

A low-cost circuit board design is presented, which in one embodiment is smaller than a credit card, for biopotential (EMG, ECG, or EEG) data acquisition, with a focus on EEG for brain-computer interface applications. The device combines signal conditioning, low-noise and high-resolution analog-to-digital conversion of biopotentials, user motion detection via accelerometer and gyroscope, user-programmable digital pre-processing, and data transmission via Bluetooth communications. The full development of the device to date is presented, spanning three embodiments. The device is presented both as a functional data acquisition system and as a template for further development based

on its publicly-available schematics and computer-aided design (CAD) files. The design will be made available at the GitHub repository https://github.com/kellygs/eeg.

Introduction

A brain-computer interface, or BCI, is a modality for human-computer interaction whereby a person may control an external device using brain signals without muscular intervention. The brain signals of interest may be time-varying electrical potentials generated by firing neurons, variations in the brain's magnetic field, or changes in local blood flow, all of which are correlated with different mental states. One of the most widely used signals is the electroencephalogram (EEG), since it has excellent temporal resolution, can be measured non-invasively, and is comparatively inexpensive and simple to acquire.

BCIs are often the best, or even the only, option for a variety of diseases and traumas. They are of the few options available for victims of so-called "locked-in syndrome," a state in which voluntary muscle control is lost over the entire body. This can be a unique disease or a symptom of advanced amyotrophic lateral sclerosis (ALS). It was estimated that approximately 30,000 Americans had ALS in 1999, with an annual incidence rate of one or two cases per 100,000 people [1]. BCI is also a promising avenue for prosthetic limb technologies, an area of particular interest to the U.S. military due to the increasing problem of limb loss among troops returning from Iraq and Afghanistan. For instance, according to the Armed Force Health Surveillance Center, in 2011, 240 deployed troops required upper or lower limb amputation, higher than any year prior. Furthermore, the total number of amputations occurring during all Iraqi and

Afghan conflicts was reported at 1,599 as of May 3, 2012 [2]. Outside of battle, over 1.7 million Americans live with at least one lost limb [3]. One study examining the prevalence of U.S. limb loss up to 2005 estimated that as many as one in 95 Americans may have had an amputation by the year 2050 [3]. With such need, it is no wonder that BCI is an area of active research.

In the following, I present background on the EEG, especially in forms suitable for use as a practical BCI (i.e. wearable, wireless systems). I then move on to discuss the design rationale behind the prototype device presented herein, along with its design evolution over time and its performance metrics as compared to a commercial system. I conclude with future directions for the project.

Background

EEG and its Origins

The first electroencephalogram acquired from a human being is attributed to Hans Berger, a German psychiatrist, who in 1929 published his findings on electrical activity of the brain recorded from the scalp [4]. Despite initial skepticism from the scientific community, EEG has proven to be one of history's most important contributions to clinical electrophysiology. Analysis of the EEG allows for noninvasive determination of a number of clinically relevant parameters, including seizure localization and classification [5], but also the detection of drowsiness [6], certain affective states [7], and motor imagery [8], among others. It has also become a tool for neurofeedback, which has shown potential as a clinical tool for enhancing self-regulation and inducing neuroplasticity [9].

The EEG originates from the formation of dipoles within the brain as the result of neuronal ion flow. Changes in relative ion concentration, and thus in net charge, between the intracellular and extracellular spaces generate electric fields whose orientations are determined by the orientation and geometry of the neurons from which they originate. These electric fields cause wavelike movement of charge, known as volume conduction, through the cranial contents and the cranium itself, ultimately resulting in a distribution of nonzero electrical potentials on the scalp. Although these potentials are present, the varying orientations of the neuronal dipoles, the large

number of different signal patterns being generated, and the distance over which any given signal must propagate through volume conduction to reach the scalp invariably produce a greatly attenuated and spatially smeared representation of the brain's electrical activity. Despite this, sufficiently sensitive equipment can detect resultant changes in voltage across the scalp, albeit with poor spatial resolution.

EEG Signal Acquisition

The EEG is acquired through the placement of electrodes on the scalp, which follow the scalp's change in electrical potential. The potential difference between electrodes can then be amplified to a workable level, at which point it is typically digitized and stored on a computer for analysis.

Because the EEG is a tiny signal on the order of microvolts in amplitude, owing to the summing and blurring effects of volume conduction, acquisition of good-quality EEG signals has stringent requirements on the electrical impedance of the body-electrode contact and the noise resistance of the transmission line between the electrode and the amplifier. Minimization of the scalp-electrode impedance is typically acquired through mechanical abrasion to remove the stratum corneum, the high-impedance upper layer of the epidermis consisting of dead skin cells, followed by application of an ionic gel between the electrode and the skin. Hairy areas such as the head pose a challenge to this impedance minimization process, usually necessitating more gel than would otherwise be used; in cases where maximum signal quality is required, the hair is typically shaved. Although research is ongoing into dry, through-hair

electrodes that match the interface impedance (and thus signal quality) of the traditional type, and some have even made it to market, wet electrodes remain the gold standard for clinical EEGs.

The amplifier itself must also contribute as little noise as possible. Although past amplifiers and analog-to-digital converters (ADCs) tended to run on high-voltage supplies—e.g. ±12V or ±5V—necessitating very high gain, modern amplifiers are capable of rail-to-rail operation from a single-ended voltage supply as low as 5V, 3.3V, or 1.8V, and digital logic levels continue to fall. As a result, much lower gains can be used. This effect is compounded by the advent of ultra-low-noise amplifiers and modern analog-to-digital (A/D) techniques that allow acquisition with up to 24-bit nominal precision. Sigma-delta ADCs, for example, drastically oversample the acquired signal and then use noise-shaping filters and decimation to produce a lower-rate signal with high precision; their inherent low-pass filtering mean that analog anti-aliasing requirements are far less strict than in traditional ADCs. These innovations, combined with improvements in wireless communication technology, mean that EEG amplifiers—once bulky and high-powered devices—can now be miniaturized to the point of being wearable devices.

Wireless EEG Acquisition Devices

The benefits of a small, wireless EEG system are numerous, both medical and non-medical. An ambulatory EEG device either with wireless connectivity to a host computer or the Internet, or with sufficient local storage to record large amounts of data in a home setting, would be extremely useful for clinicians in that they could learn about

a patient's EEG activity in a natural setting, improving patient outcomes. For instance, sleep activity could be monitored at home, or pre-ictal EEG could be analyzed for a patient who experienced a seizure during their everyday routine rather than at a hospital. A wearable EEG system could also enable a more practical non-invasive brain-computer interface in disabled patients, such as those with ALS or MS, than the traditional bulkier designs. On the other side of the coin, a wearable EEG system could enable a wide array of recreational applications, from simple focusing games to neurofeedback for relaxation or simply as a novel control method for external devices. Such devices would need to be as easy as possible to use, which means light weight and long battery life.

Some commercial devices are already available to meet this market. One is the B-Alert X systems from Advanced Brain Monitoring [10], which feature 3, 9, or 23 channels of EEG and 1 auxiliary differential channel, along with an accelerometer for head movement detection. The X10, the midline model with 10 channels, claims power consumption of 40 mA at 3.7V, with a standard battery life of 12 hours and an optional battery extension giving 24 hours of battery life. Advanced Brain Monitoring also sells the Stat-X series with the same features as B-Alert X, but approved for clinical use. All the devices use a proprietary 2.4 GHz RF link to a host computer, however, which limits their interoperability or use for device control. They give no price on their website, suggesting a very expensive system.

Another such commercial device is the EPOC from Emotiv [11], which uses 14 electrodes placed according to the international 10-20 system on an easily donned headset, along with a MEMS gyroscope for head position information. The intent is to

interpret the EEG (transmitted to a host computer via proprietary 2.4 GHz RF) using a suite of affective classification algorithms as a novel form of human-computer interaction. The EPOC retails for only $299, making it one of the few affordable wireless EEG systems on the market. By default, however, the raw EEG signals are not exposed to the user; this requires purchasing a license and SDK to develop novel uses or do research with the device. This costs an additional $451, making such activities a bit further outside the reach of the average consumer. There is some question as to the quality of the EPOC's data compared to a medical-grade EEG system [12] but an increasing number of researchers have used it for BCI experiments [13].

NeuroSky manufactures the MindWave Mobile headset, which centers around an EEG application-specific integrated circuit (ASIC) that compactly acquires and interprets EEG with low power consumption [14]. This ASIC, called TGAT, includes on-chip bandpass filtering down to the EEG band, mains noise notch filtering, and individual frequency band extraction. It also performs an unknown proprietary algorithm for quantifying attention and relaxation. The headset is made easier to use by the fact that it uses Bluetooth as its wireless protocol, and thus it is potentially more compatible with existing wireless devices. However, the MindWave Mobile's single dry electrode is located on the forehead, resulting in extreme signal contamination by EMG, and the frequency band output variation of the device was found in one instance to be the same whether or not the headset was being worn [15].

Lin et al. conducted a survey of published work on wireless/wearable EEG systems in 2010, with a focus on BCI applications [16]. They report a design published in 2002 by Cheng et al. for acquiring EEG and transmitting it to a computer for BCI

applications, but they give no details on the implementation of their device, focusing instead on the processing paradigm and its results [17]. In a 2007 paper, Matthews et al. developed a low-power data acquisition system and wireless transceiver to operate with an experimental capacitive dry electrode design [18]. They report that their design operated off of two AA batteries for 72 hours. However, the design was proprietary (a result of R&D by Quantum Applied Science and Research) and no details on its construction, weight, or potential cost were given. Lin et al. reported in 2008 on their embedded BCI that used a Texas Instruments applications processor including both an ARM9 core and a 16-bit low-power DSP core [19]. Although they give a reasonable amount of detail regarding what components went into their system, the processor module on which it is based is no longer available from TI [20].

One notable aspect of all the wireless EEG systems observed in the Lin review, as well as in the literature at large, is the lack of detailed descriptions of the devices, their performance, and their construction. This is understandable, given the all-too-certain desire of the authors to preserve their intellectual property for later lucrative patenting. However, this tends to result in multiple concurrent efforts being expended redundantly across multiple research teams; one need only examine the volume of independent groups represented in a Google Scholar search of “wireless EEG BCI” to ascertain this fact. This restricts progress to the teams with prior knowledge of how to build these designs and/or the funds to quickly get up and running with outside assistance. At the time this thesis was begun, only one EEG system was fully open, in the sense that all hardware schematics, software, and firmware were freely available online: openEEG [21]. This project, first released around 2002, allows one to build a

low-cost 2-channel desktop EEG system for $200-$400, depending on part sourcing and whether or not electrodes are bought or made oneself. However, the system is not at all wearable and has no wireless component. This is due in large part to the now-antiquated electronics used in the design. This thesis thus set out to fill in the wireless/wearable open-source EEG gap.

One note before continuing: in parallel with this thesis, a group planned and successfully Kickstarted a very similar system known as OpenBCI [22]. This system uses much of the very same hardware applied in this thesis, works as an add-on board for the popular Arduino open-source microcontroller platform [23], and promises to be very successful, given the amount of interest it has generated and the significant funding it has behind it. Although OpenBCI in its current incarnation does not have inbuilt wireless communications, the group states that they have a wireless and battery-powered system in the works. It is very likely that OpenBCI will become the future platform of choice for open-source EEG experiments and homebrew development.

Design Process

Considerations and Parameters

The initial design parameters were that the device should be *wireless*, to enable user mobility; that it should be as *small and lightweight* as possible, implying a high level of component integration and low power consumption to enable a relatively small battery; and that it should be capable of performing at least some basic amount of *digital processing* on the signal it acquires, such as band power extraction, to reduce or eliminate the device's dependency on a host computer and thus further enhance user mobility. As will become clear over the course of this chapter, not all of these parameters were met in a single design, resulting in differentiated designs separately optimizing size and processing capability.

Openness

One aspect of this design that evolved over the course of reviewing the literature was the importance of making the design specifications freely available. Although many researchers have previously developed wireless EEG systems for BCI applications, and some were even commercially available, no finished designs at the time this project was begun had been made truly "open"—no circuit schematics, board layouts, or source

code were posted anywhere for general perusal. This made accurately assessing the state of the art much more difficult, but presented a gap in the field that could be met. Although the basic functionality of the final design isn't completely novel, its near-uniqueness lies in the fact that its hardware and software components are available for free download by anybody. I made the decision to make my design as "open" as possible in the following ways:

- Use only of off-the-shelf components that are openly documented and accessible to hobbyists. This also means that programmable components (e.g. microcontrollers) must have free or low-cost development tools. This has the added benefit of making my own development process much cheaper and easier, but its primary purpose was to ease collaborative modifications of the design in the future.
- Publishing of the entire design—hardware schematics, board artwork, and firmware—to a GitHub repository for public perusal. This would greatly increase the potential value of the design simply by allowing more people to build upon it, if they so choose.

Although use of VLSI hardware design (i.e. custom chip design) doesn't strictly preclude openness with regards to sharing results—the design could, for example, be implemented on an FPGA and the HDL code could be made freely available—full-featured FPGA development environments are quite expensive and not quite in the spirit of "open source" design. It was thus determined that signal processing would take place wholly in software, which necessitated selection of a suitable microprocessor, as described in the following section.

Beaglebone and Beaglebone Black

To allow for sophisticated signal processing in software, it was desirable that a high-speed microprocessor capable of running a full-featured operating system be included in the design. With a desktop or laptop PC out of the equation due to the requirement for mobility, some kind of embedded processor was desired. Smartphones were considered as a platform, but ultimately rejected for a number of reasons:

- A smartphone platform excludes users who do not already own smartphones (although this number is admittedly dwindling every day)
- A smartphone platform would most likely exclude iPhone users during early development, since iOS presents relatively more obstacles versus Android to app development and Bluetooth communications (excepting Bluetooth Low Energy, which was much less mature at the time of initial design planning)
- A local, wired connection to the signal acquisition hardware would be ideal, since it would contain all the components of a BCI system, minus the electrodes, in a single package, and would save energy by eliminating wireless data streaming

Since embedded processors and their associated memory chips are typically in difficult-to-solder packages and can be difficult to work with, requiring close attention to board layout for high-speed signals, a preexisting single-board computer was sought as a host processor. Popular single-board computers included the Raspberry Pi [24] and the Beaglebone (along with its upgrade, the Beaglebone Black, which was released

during design planning [25]). Although the Raspberry Pi was, and remains, the most popular single-board computer within the maker community, it was outmatched in compactness and expandability by the Beaglebone devices.

The Beaglebone Black (BBB) was ultimately selected as the computational engine for the design. It is a 3.4” x 2.15” single-board computer with HDMI, USB host, and Ethernet capability. Its processor is a 1 GHz ARM Cortex-A8 and it has 512 MB of RAM, along with 4 GB of non-volatile flash memory and microSD card support. It has 92 I/O pins for external interfaces and is capable of interacting with devices that would normally require a deterministic microcontroller, due to its two independent on-chip Programmable Real-time Unit Subsystems (PRUSSs).

The Beaglebone and BBB are specifically meant to work with expansion boards, called “capes,” which plug into their I/O sockets and provide additional functionality. For example, there are capes containing Wi-Fi radios, motor control circuitry, and AA battery slots [26]. Capes are recognized by the host using configuration settings loaded onto an EEPROM chip, which is thus required for all capes. This project’s design could therefore easily couple with the BBB simply by designing it as a cape.

The BBB’s current consumption, rated at a typical 210-460 mA depending on activity, would pose an obstacle to wearability if battery life were to be maximized. Thus a dual-mode PCB was envisioned: the device could have its own low-power microcontroller onboard so that it was capable of operating standalone with limited or absent processing of acquired data, or it could plug onto the BBB and gain additional processing capacity at the expense of battery life.

It is important to note that, due to time constraints, BBB software was not developed as part of this project, which instead focused on refining the standalone aspect of the design (i.e., offloading the signal processing to a computer via wireless communication). However since the BBB runs Linux, existing BCI or EEG acquisition software may be adapted for this purpose. For example, BCI2000 [27] in its original incarnation is known to work on a 1.4 GHz single-core machine with only 256 MB of RAM [28]. Open Ephys, an open-source hardware/software solution for electrophysiology experiments such as intracellular recordings, includes a lightweight customizable GUI with built-in support for data processing blocks [29]. As part of a side project, a rudimentary data engine was established by Jay Freitas for reading from the BBB's UART port and displaying 8 channels of data; however, it has not yet been expanded upon, and the display GUI provides no means of bidirectional communication with the ADS1299. Robust Beaglebone software would be a clear direction for further development.

Initial Component Selection and Evaluation

Before any custom circuit design was attempted, the major individual components had to be selected. Once these major components were known, evaluation boards for each could be purchased and linked together to build a prototype system. This process was carried out using the design criteria previously listed, as presented in Table 1.

Function	Part Selected	Justification
Signal acquisition	Texas Instruments ADS1299 analog front-end	Signal conditioning and ADC on single chip: eases design and consumes less board space than discrete solution
System control	Atmel AT32UC3L064 32-bit AVR microcontroller	Low power consumption, high speed (up to 48 MHz), small package size, direct memory access engine for fast peripheral communications, native DSP instructions, free development environment (Atmel Studio)
Wireless communications	Microchip RN-42 Bluetooth module	Widely used and popular among hobbyists, simple interface, pre-certified by FCC, no RF design needed, Bluetooth protocol allows simple interface with common hardware like PCs and Android phones

Table 1: Part selections for initial prototype

The ADS1299 is an 8-channel, 24-bit, low-noise analog front-end for biopotential measurements, specialized for scalp EEG applications. It provides both analog signal conditioning (i.e. low-noise programmable-gain amplifiers) and analog-to-digital conversion in a single package. All 8 channels are fully differential and sampled simultaneously, and the device may be daisy-chained and synchronized with additional ADS1299s to expand the number of channels almost arbitrarily. Its high bit resolution gives it both precision and dynamic range, allowing it to capture signals as high as 4.5 V and as low as 0.5 μV. This high input range means that it can easily be repurposed to capture various electrophysiological signals other than EEG, such as EOG, EMG, or ECG. It can also sample at rates from 250 Hz to 16 kHz and includes on-chip circuitry for setting the patient bias voltage, along with lead-off/lead-impedance detection. Finally, it incorporates a sophisticated multiplexer that allows for dynamic selection of

reference and bias electrodes in the event of lead-off or excessive lead impedance, along with an array of diagnostic modes for (e.g.) measuring the bias voltage, measuring the die temperature, or performing calibration and internal noise tests.

Although the ADS1299 is expensive ($58.14/chip in quantities below 10 from Digi-Key), it more than makes up for this in board space reduction due to the sheer amount of features. Only passive components and two external op amps per ADS1299 (if multiple AFEs are used) are necessary for buffering the reference electrode and driving the cable shield, respectively, and single-package dual op amps are widely available.

Selection of the system microprocessor/microcontroller was the most time-consuming decision. The processor needed to consume as little power as possible and yet have enough processing capability to handle, at the very least, real-time FIR filtering of a reasonable-length signal. It also needed to be both reasonably easy to program (high-level languages like C/C++ were a must) and inexpensive in both time and money to develop for (low-cost or free development tools, freely available libraries for on-board peripherals and, if possible, for signal processing).

The initial desire to make the design open-source led toward an Arduino-compatible microcontroller, but the lack of computational power in the 8-bit Arduinos and the excessive chip size and power consumption of the 32-bit Arduino Due ruled it out as a useful candidate for a battery-powered wearable system. I leaned toward 32-bit microcontrollers since they would be able to handle the 24-bit data from the ADS1299 more quickly. Of those I could find during my initial search, only Atmel’s 32-bit

microcontrollers had a completely free development environment. Atmel offered two families of MCUs that had specialized DSP instructions: those with the AVR UC3 core, and those with the ARM Cortex-M4 core. Of these, the former was older and more well-established, which I assumed would be a benefit in terms of support and chip availability.

It should be noted at the outset that the selected microcontroller may not have been the best for a number of reasons. The AT32UC3L064 has only 16 KB of SRAM, which limits the size of its data buffers and thus the amount of signal processing that can be done on-chip. More importantly, however, its documentation and support (both professional and from the user base) are lacking compared to comparable but more popular chips such as the wide variety of ARM Cortex-M microcontrollers. Although I initially supposed that the chips' being slightly older than Atmel's Cortex-M devices would make them more established and thus give them a wider support base, this was discovered after a long and frustrating period of development not to be the case.

Future modifications of this design should upgrade to something with a wider following, perhaps something based on the Teensy 3.1 (a Cortex-M4 device with support for the Arduino IDE). Although the Teensy designs are not completely open-source, they are very popular within the hobbyist and open-source hardware community due to their Arduino IDE support, and thus this drawback might be acceptable.

The RN-42 is a Bluetooth pre-certified module for drop-in replacement of serial (RS-232) cables. Because it is pre-certified, it can be used in end devices without additional certification by radio emissions regulatory bodies such as the FCC. It

interfaces with the Universal Asynchronous Receiver/Transmitter (UART) of a host microcontroller and converts data bidirectionally between the wired CMOS/LVTTL-level RS-232 protocol and the Bluetooth 2.1 SPP (Serial Port Protocol). The module contains on-board flash memory for settings and Bluetooth stack storage, along with a Bluetooth system-on-chip that executes the stack and interprets data from the UART. The RN-42 is a Bluetooth Class 2 device, meaning that it emits up to 2.5 mW of RF power and thus has a typical range of about 10 meters. The device is well established within the hobbyist community due to its ready availability on SparkFun, a popular DIY electronics website.

Evaluation boards were purchased for each of the core parts. For the microcontroller, the specific board selected was the UC3L Xplained, along with an AVR Dragon programmer board for programming and debugging. The RN-42 was evaluated using the popular BlueSMiRF Silver board from SparkFun. In the case of the ADS1299, only the official evaluation module from TI was available, and so that was used. All additional parts of the later custom-PCB prototypes (voltage regulators, passive components, etc.) were selected using the reference schematics for these evaluation boards, which greatly eased the design effort.

Because the device is coupled through a low-impedance path to the user's scalp, some measure of protection is needed to ensure user safety. In addition, the circuitry should be protected against electrostatic discharge (ESD).

The device is battery-powered, which reduces the need for on-board protection circuitry. For the initial prototype, the problem of user isolation during battery charging

was sidestepped by simply not using the device while the battery charges. To prevent taking up extra room on the device's PCB, isolation should ultimately be implemented using an isolated USB cable. This type of cable contains integrated isolation circuitry.

All analog lines connecting to the user are current-limited as an inherent aspect of the passive antialiasing filters. This provides two-way protection: both the user and the device benefit from the limited current. However, ESD can generate voltages too great to allow the use of current-limiting resistors alone for device protection, since larger resistors produce more thermal noise and must be matched with impractical precision between differential inputs. As an additional safeguard, ESD protection diodes were used. In general, an ESD solution for precision analog circuitry should have the lowest possible leakage current and capacitance in order to prevent signal distortion. Texas Instruments' TPD4E001 is a quad-channel ESD-protection diode array that meets these requirements, with less than 1 nA of leakage current and 1.5 pF I/O capacitance. It is available in a number of small packages, down to 1.6x1.6 mm. Their layout causes excessive voltage spikes to be harmlessly redirected to one of the power rails, where they are suppressed by a decoupling capacitor.

First Prototype: Brainboard R0

The first prototype, the Brainboard R0 (revision 0), was meant as a proof of concept and also to test the feasibility of assembling a surface-mount PCB in-house. It used the standard Beaglebone cape form factor, with the intention that it would be able to operate in two modes: either as a standalone board capable of transmitting EEG data

over a Bluetooth link, or as a cape for the BBB capable of sending and receiving data to/from that device over one UART link, then relaying commands from the BBB to the Bluetooth module over a second UART.

The R0 was not intended as a finished design, and thus it did not include all the necessary components to generate every power supply on-board. The ADS1299's analog circuitry was powered by an off-board 5V supply, which was post-regulated using an LDO linear regulator to reduce switching noise that would be introduced from the BBB. All digital circuitry, which comprised the remainder of the circuitry on the board, was powered by an off-board 3.3V supply. Both of these supplies were broken out on the BBB I/O headers, so the design was essentially dependent on either the BBB or some other external power supply in order to run. All evaluation was done using a bench-top power supply and jumper wire.

Initially, it was planned that schematic creation and PCB layout would be done in Cadsoft's EAGLE program, which is a program I was familiar with and which has a freeware version that is very popular in the maker community. However, it quickly became apparent that the complexity of this design and the requirement for proper shielding of analog signals was going to require at least four copper layers, and EAGLE's freeware edition can only generate two. Since the non-freeware versions of EAGLE that could be purchased by the university are expensive (the lower-cost hobbyist version is for individual use only), an alternative had to be pursued. This came in the form of KiCAD, an open-source suite of schematic capture and PCB layout software.

One key decision that had to be made in this design was whether to break out both the positive and negative inputs to the ADS1299 for every channel. Referencing all the positive inputs to a single negative input (the “reference channel”) is standard procedure for most EEG systems, and it would also greatly simplify board layout. This was therefore the option chosen for R0.

The onboard microcontroller was to be programmed and debugged using a 10-pin JTAG port. This would be connected to the AVR Dragon, which in turn would be connected to a PC via USB cable.

Assembly Process

The PCBs were ordered from OSHPark, a low-cost board fabrication service. Because the lab did not have a means of reflowing the surface-mount components, it was necessary to affix them by hand using a soldering iron. Although this process was time-consuming and error-prone (initial assembly, plus finding and repairing hidden solder bridges and cold joints, took over a week) it was ultimate successful in producing a functional, if aesthetically imperfect, board.

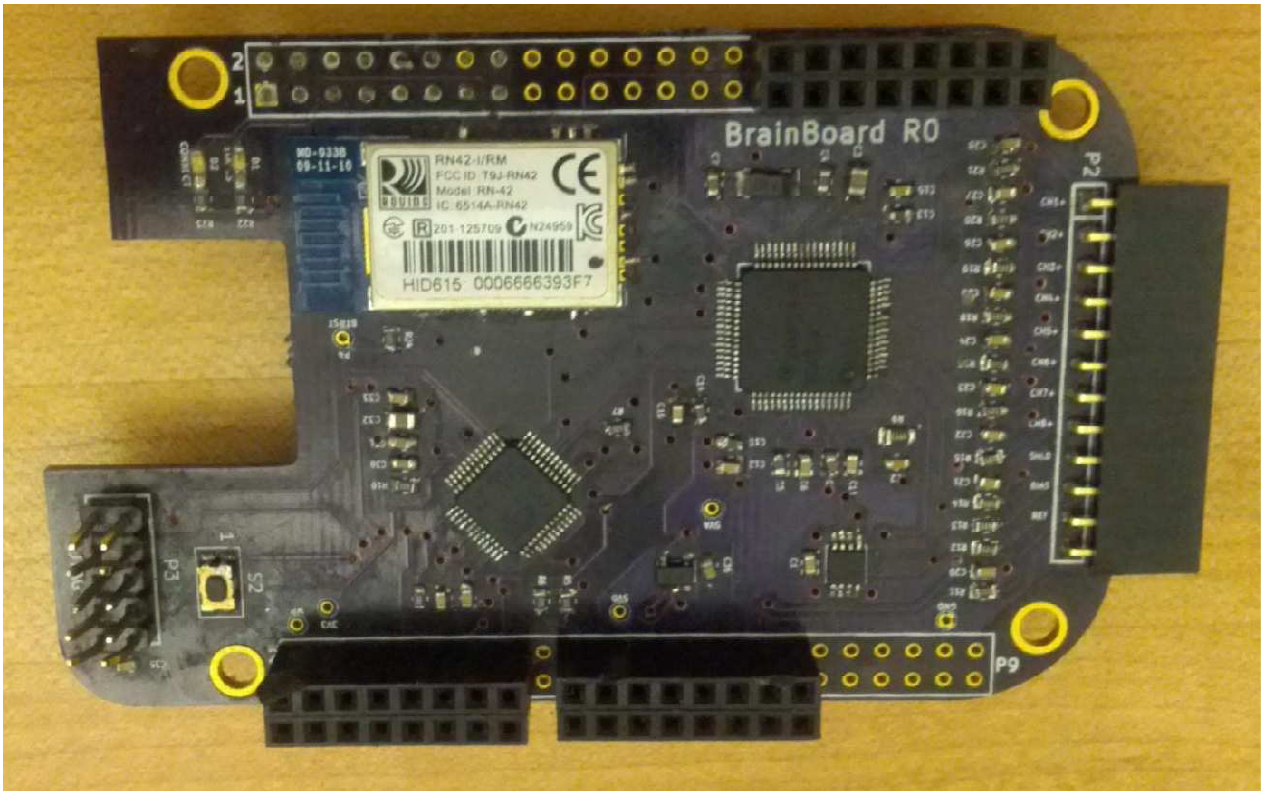

Figure 1: Brainboard R0

Software and Firmware

Firmware was developed in C using the free Atmel Studio IDE, and debugged/flashed onto the board using the AVR Dragon connected to the 10-pin JTAG

port. Atmel's freely available set of libraries, known as the Atmel Studio Framework (ASF), was used as much as possible in order to reduce development time and effort, both for me and for future developers. Using the ASF was also an attempt to ensure maximum cross-platform code compatibility with other Atmel products, in the event that another microcontroller was used in a future revision. All firmware for the final design is given in **Error! Reference source not found.**.

The ADS1299 is controlled via the SPI protocol and supports 10 commands. These are given in Table 2, which is derived from page 35 of the device datasheet [30].

Command	Description	First Byte	Second Byte
System Commands			
WAKEUP	Wake up from standby mode	02h	-
STANDBY	Enter standby mode	04h	-
RESET	Reset the device	06h	-
START	Start and restart (synchronize) conversions	08h	-
STOP	Stop conversion	0Ah	-
Data Read Commands			
RDATAC	Enable continuous data read mode	10h	-
SDATAC	Disable continuous data read mode	11h	-
RDATA	Read data by command	12h	-
Register Read Commands			
RREG	Read from register(s)	2Rh	0Nh
WREG	Write to register(s)	4Rh	0Nh

Table 2: ADS1299 command definitions

The register read commands differ from the rest. They are 2-byte commands; the first byte signifies dataflow direction (read or write) with its 6^{th} and 5^{th} bits, while bits 4 through 0 (indicated by "R" in Table 2) indicate the register address of the first register to be accessed. The second byte's lower 5 bits then indicate how many registers to access sequentially after the first register. In this way a single command can be used to initiate multiple register reads/writes. The WREG command is always followed by at

least one more byte, which contains the data to be written to the selected register. The firmware and software implemented in the Brainboard designs does not support multiple register accesses in this fashion from the host computer; the maximum number of bytes in a received command is 3. Writing or reading multiple sequential registers must be done with separate WREG/RREG commands.

The code is entirely event-driven. On power-up, the MCU initializes its on-chip peripherals (clocks, DMA controller, data and auxiliary UART, and SPI), and then verifies that the ADS1299 is working properly by requesting its chip identifier byte, which is specified in the device datasheet. If this byte is wrong, the MCU sends a message to this effect on UART and goes into a low-power idle state. Otherwise, it initializes the ADS1299 registers such that, upon receipt of the START command, it will begin sending data continuously at a rate of 250 Hz. The MCU then goes to sleep and waits for receipt of a three-byte sequence on the data UART, corresponding to the maximum number of bytes in an ADS1299 SPI command. These three-byte commands come from the controlling computer and are instantly relayed over the SPI bus, allowing the computer to reprogram the ADS1299 if necessary. More importantly, the controlling computer sends the START command to begin acquiring data.

Since the ADS1299 is put in continuous read mode, only one START command needs to be sent. The MCU sleeps until the ADS1299 asserts its DRDY (data ready) pin, which triggers an interrupt. After receiving this interrupt, the MCU reads a 3-byte status word and eight 3-byte data words from the ADS1299, stores them in a buffer to be transferred over the data UART, increments a counter, and then compares the counter to a threshold. If the counter has reached the threshold, it initiates DMA transfer

of the buffer over the data UART and goes to sleep. Otherwise, it simply goes to sleep and waits for the next DRDY assertion.

Importantly, the UART connection between the MCU and the RN-42 must use some form of hardware flow control; otherwise, the RN-42 can quickly become overwhelmed by data coming in at a baud rate greater than 9600. Hardware flow control, in this and most cases, refers to the use of two out-of-band signals, designated RTS and CTS, as the hardware layer of a handshaking protocol. These are crossed over between endpoints, meaning that RTS of one endpoint connects to CTS of the other, and vice versa. In the null state, each endpoint holds its CTS line low, meaning that it is ready to receive data. When an endpoint's input buffer is almost full, it asserts its CTS line, which the other endpoint uses to gate its transmissions. Asserting CTS on a completely full buffer is likely to drop data, since it is very possible for the other endpoint to have sent some bytes at the same time the control signal was sent. Transmission to the overwhelmed endpoint will thus halt until its buffer has cleared, at which point it will again clear its CTS line. From the viewpoint of the microcontroller communicating with the RN-42, the program must halt all transmissions upon assertion of the MCU's RTS line (connected to the RN-42's CTS line), and then resume them once RTS is cleared.

Since the MCU is much faster than the RN-42 at data handling, and since only very small amounts of data move from the RN-42 to the MCU, unidirectional flow control is all that is really needed. This is simpler to implement, since it doesn't require an estimation of what level constitutes an "almost full" UART buffer. This is a useful point to keep in mind for implementation on simpler microcontrollers without hardware support

for RTS/CTS handshaking; however, the UC3L has such support, and thus all flow control is handled transparently.

Data is transmitted in 42-byte packets, and the UART baud rate is the RN-42's default 115,200 bits/s. To minimize power consumption, data is sampled from the ADS1299 at the minimum rate of 250 Hz. Although this can be increased up to 16 kHz, doing so provides no clear advantage for BCI applications, since all the relevant frequency bands are below 30 Hz, giving plenty of Nyquist headroom at even the minimum data rate.

On the host computer side, the BCI2VR MATLAB program was used [31]. Acquisition in this environment consists of starting the Data Acquisition module and loading a "setup file," which is an m-file that contains the information needed to open a connection with the Brainboard: the MAC and channel numbers for the RN-42 Bluetooth module, the number of channels being used (up to 8), and the scaling factor to convert the ADS1299 output integers to microvolts. An example setup file is given in **Error! Reference source not found.**. Once the setup file is loaded, BCI2VR will attempt to open a connection and program the ADS1299 with its default settings: gain of 24 and 250 Hz sampling rate. If this fails, an error message will be thrown and the process will have to be restarted. Otherwise, the connection is opened and the user may proceed by pressing the green triangle ("play") button on the BCI2VR GUI, which begins display of the data. Actual acquisition streaming is begun as soon as the connection is successfully opened.

An additional button is presented in the GUI for turning on the ADS1299's internal calibration signal on all channels. This is a square wave of amplitude 1.875 mV

and frequency of approximately 1 Hz (2.048 MHz / 2^{21}). Since the signal is at known amplitude and also is generated inside the chip, it can be used to simultaneously calibrate the device and determine if a fault in the signal chain is rooted in firmware or in a faulty hardware connection. Pressing this button once resets the ADS1299 and programs the MUX bits for all channels such that they are internally connected to the test signal generator; pressing it again resets the chip and returns it to normal operation.

The ADS1299 contains a huge array of other features that could be conveniently controlled using the BCI2VR Data Acquisition GUI, such as lead-off detection and impedance monitoring. Although these have not been fully implemented in the current version, it would be trivial to do so using the calibration button implementation as a reference.

Discussion

As a proof of concept, Brainboard R0 was successful. However, because it lacked a way to power itself from a battery, it was incapable of running in standalone mode without extra circuitry. This was done for the first prototype as a temporary measure, so as to avoid designing a complex circuit that could coexist with the BBB's power management system (including battery detection and charging). The difficulty of reconciling these two power management systems without introducing expensive redundancy was a strong impetus for the later design differentiation (see Design Differentiation below).

Furthermore, the design had a serious layout mistake that rendered the ESD protection diodes useless. The particular package selected for these diodes was chosen

because it was the largest package with external leads, and thus it would be easiest to work with. Unfortunately, the pinout differed from package to package, and when I created the schematic symbol, I accidentally used the pinout from a similar-looking package. As a result, the diodes were connected incorrectly to the remainder of the circuit, with the effect that shorting all the signals together (as was done in the externally shorted noise test) actually shorted the 5V power and ground rails together. This destroyed most of the ICs on the board, and they had to be replaced. Further tests of the board had to proceed with the diodes uninstalled.

Once basic functionality of the EEG acquisition system was confirmed, further revisions were undertaken in order to correct the above issues.

Second Prototype: Brainboard R1

The second design improved on the layout issues from R0, and expanded its functionality by adding inertial sensors in the form of the MPU-6050, a 16-bit, 6-axis digital accelerometer/gyroscope with an I^2C interface. It was further improved by altering the way the ADS1299 inputs were broken out. Two of the channels were made differential; i.e., for channels 1 and 2, both the positive and negative inputs were broken out for electrode connection. The rest of the negative inputs were hard-wired to the common reference electrode input pin, SRB1. This allowed the ADS1299 to be placed in differential mode overall, producing the effect of two differential channels and six single-ended channels. The two differential channels were for use as EOG electrodes, which would allow simpler removal of eye-movement artifacts from recordings. If the

differential capability was undesired, the negative inputs could easily be overridden simply by programming the ADS1299 to operate in single-ended mode.

The reason for including the MPU-6050 was to allow the device to track head/body movements, both for primary measurement and for decorrelating the EEG signals to eliminate motion artifacts. As primary measurements, linear and rotational acceleration of the device could be used as additional inputs or as fallbacks when the EEG signals could not be successfully analyzed, creating a hybrid BCI system.

This design also broke out the SPI signals (and the MPU-6050's I^2C signals) to the BBB headers. This was done primarily for debugging reasons, but it also opened the possibility of controlling those chips directly from the BBB without going through the microcontroller. In this case, a board intended purely for use as a BBB cape could be made cheaper by not populating the microcontroller.

The decision on how to reconcile the need for an independent power supply for standalone mode with the BBB's onboard power management unit and regulators was to continue to leave off the power regulation from the R1, and develop a simple add-on board with a battery charger and regulator. The 5V supply, previously taken from the BBB's 5V pins, was be replaced on the R1 by a 2.5V regulator, a switched-capacitor voltage inverter, and a -2.5V regulator, producing a split ±2.5V supply for the ADS1299. These are all derived from the 3.3V regulated supply generated off-board. This split-supply configuration means that the mid-supply bias will keep the patient at zero potential relative to the Brainboard's electronics, adding an additional measure of safety in comparison to the single-supply version's 2.5V bias.

Assembly Process

Assembly of R1 was greatly accelerated with respect to R0 due to the availability of a toaster oven, solder paste, and a paste stencil for the top side of the board. The greatest difficulty came in aligning the stencil over the board's exposed pads, since the lack of a paste printing machine meant this alignment had to be made by hand. This was still far easier than the hand-soldering process, and once the board was aligned, it could be carefully taped in place under the stencil, making the paste application process easy. Solder paste was scraped across the surface of the stencil using an old magnetic keycard, then excess paste was scraped away and saved in a small storage container for reuse. The wet paste could be easily wiped away with isopropyl alcohol and replaced in the event of a mistake, although none occurred. Each component was hand-placed onto the paste-covered pads, and then the board was heated at 450º F for approximately 15 minutes, or until inspection revealed that the paste had silvered and reflowed. Fine-pitch components like the UC3L and ADS1299 required some minor touch-up work with the iron due to bridging, but overall this process was significantly easier and faster than before.

The bottom side of the board contained only the TVS diodes and their attendant capacitors, along with a few solder jumpers. It was thus not cost-effective to order a stencil for this side, and it was soldered by hand in the same manner as R0. The larger pitch of these components and their small number meant that this process took only a few minutes.

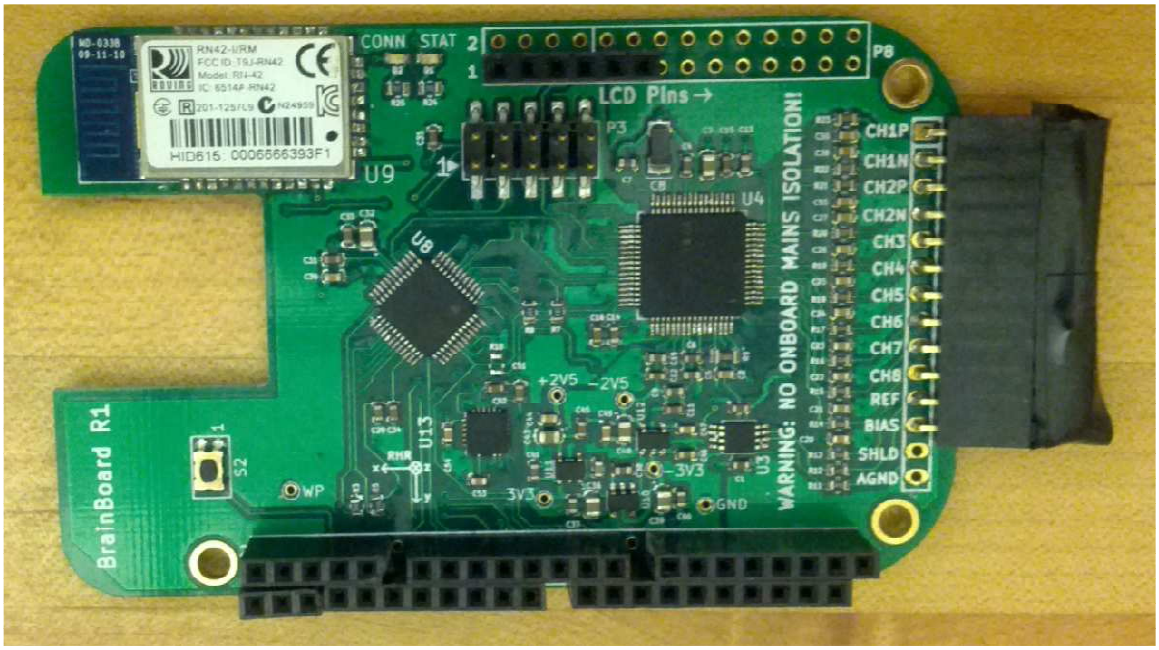

Figure 2: Brainboard R1

Software and Firmware

Firmware development to accommodate the MPU-6050 in R1 was most easily accomplished using Atmel's TWI[1] library for the UC3L, but this introduced some setbacks. The library was hard-coded to use a blocking interrupt setup: TWI interrupts would be enabled to priority level 1 at the beginning of each function in the library (and initialized in its initialization function), and each function would wait for the interrupt to trigger before returning. This meant firstly that any lower-priority interrupts would be masked by the TWI functions, and secondly that any higher-priority interrupts would themselves mask the TWI functions, causing them to hang as they waited for the interrupt flag. This had to be avoided by (1) ensuring that higher-priority interrupt code sections were rapidly executed entirely within their respective interrupt service routines, and (2) setting no interrupts to any priority lower than 1.

Since inertial readings from the MPU-6050 need only be sampled at a low rate relative to EEG signals (e.g. 10 Hz vs. 250+ Hz), it was unnecessary to code a separate interrupt for the MPU-6050's own "data ready" signal (INT). Instead, this signal is simply polled at each ADS1299 DRDY interrupt. Incidentally, this made routing the INT signal much simpler on the PCB, since it could connect to any general purpose I/O instead of one of the UC3L's limited number of external interrupt pins. This had the disadvantage of preventing the inertial data from being read independently of EEG data; however, for this application, such operation was considered unnecessary.

Battery Adapter Board

[1] , TWI, or Two-Wire Interface, Atmel's I^2C-compatible bus protocol. Its modules are implemented as two discrete entities: TWIM, or Two-Wire Interface Master, and TWIS, or Two-Wire Interface Slave. In the Brainboard designs, the MCU functions as a TWI/I^2C master device only.

Although there does exist a cape for adapting the Beaglebone and BBB to use 4 AA batteries, such a solution is not ideal in terms of size and weight. In order to accommodate a prismatic lithium-polymer battery, a minimal second board was designed. This board incorporated a battery charging IC (Texas Instruments bq24074), 3.3V linear regulator (Texas Instruments TPS73601 adjustable LDO with appropriate feedback resistors), and pushbutton on/off controller (Linear Technology LTC2951-1). A lithium-ion/polymer battery fuel gauge IC (Maxim Integrated MAX17048) was added to the board layout, but not populated due to the relative priority of getting a functional power supply versus writing firmware to detect the battery's state of charge.

The bq24074 is a load-sharing battery charger, meaning that the device could potentially be used while charging (although this would pose a shock risk unless an isolated power supply was employed). It can be pin-configured to comply with USB current limits (100 or 500 mA) and also includes resistor-programmable fast-charge current, safety cutoff time, and input current limit for non-USB-compliant applications. The equations for calculating the necessary resistor values are given below [32]:

$$R_{ISET} = \frac{K_{ISET}}{I_{CHG}}$$

$$R_{ILIM} = \frac{K_{ILIM}}{I_{IN(MAX)}}$$

$$R_{ITERM} = \frac{I_{TERM} \times R_{ISET}}{0.030}$$

$$R_{TMR} = \frac{t_{MAXCHG}}{10 \times K_{TMR}}$$

In the above, R terms represent resistances, I terms represent currents, and K terms represent empirical constants given in the device datasheet. ISET indicates variables related to the fast charge current I_{CHG}, the highest current supplied to the battery and the primary current used to return the battery to full charge; ILIM indicates variables related to the input current limit $I_{IN(MAX)}$, the limit on the amount of current drawn from the external power supply used to charge the battery, which supersedes I_{CHG}; ITERM indicates variables related to the charge termination current I_{TERM}, the current threshold below which the charger turns off during the constant-voltage phase of charging, indicating charge completion; and TMR indicates variables related to the safety cutoff time t_{MAXCHG}, after which charging ceases even if the battery voltage hasn't been restored and/or charge current hasn't yet fallen below I_{TERM}. A typical charge cycle is represented in Figure 3 below, taken from Figure 39 in the device datasheet [32].

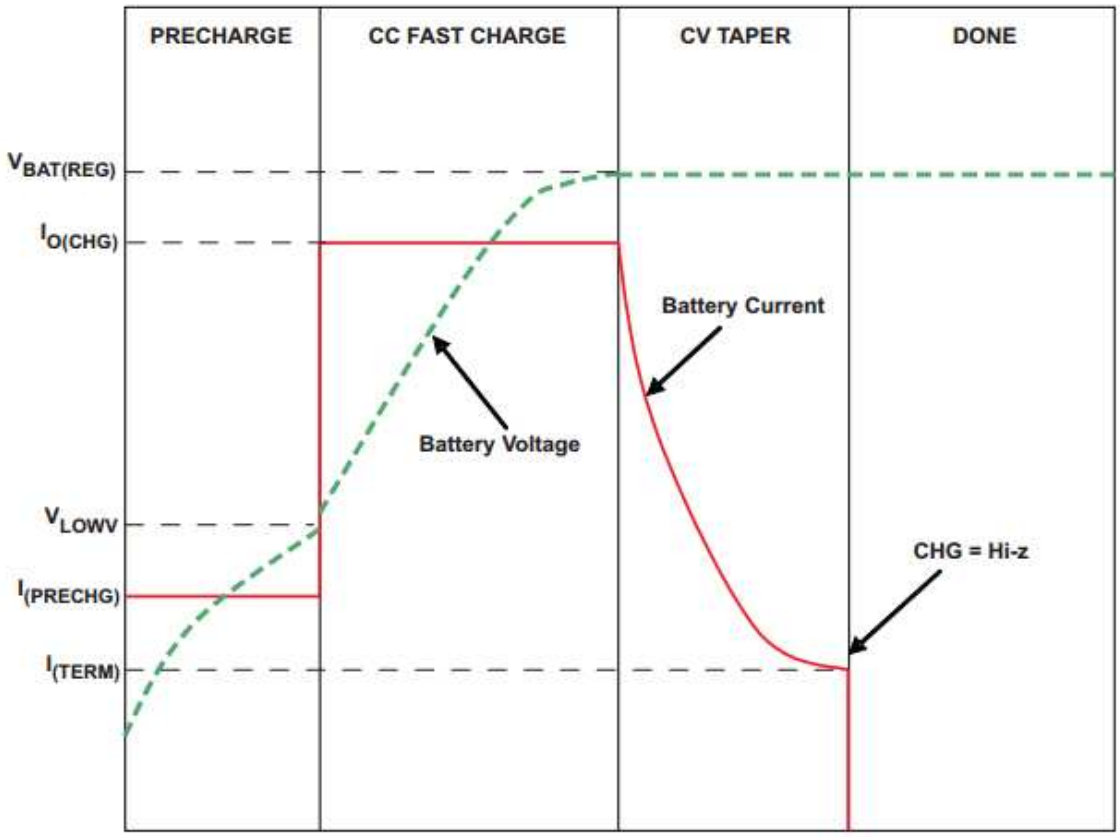

Figure 3: bq24074 lithium-ion/polymer battery charger, typical charge cycle. V_{LOWV} indicates the battery voltage at which the constant-current fast charge phase begins; $I_{O(CHG)}$ is synonymous with the larger of I_{CHG} and $I_{IN(MAX)}$.

The LTC2951 is designed to respond to a falling edge on its input, created by a momentary pushbutton, in two different ways. On power-up, the device waits for a single (debounced) falling edge on its input pin. This is considered the “power-on” press and it causes the EN (enable) pin to go high-impedance; a pull-up resistor brings the line high and enabled the system voltage regulator. When it detects a falling edge while EN is high-impedance, the device waits for a given amount of time, determined by an external capacitor (see below), and then checks the level of the input. If the input remains low, then the LTC2951 sends an interrupt signal on its ~INT pin, which may be

connected to a microcontroller or back to the ~KILL pin on the LTC2951. Regardless of the origin of the signal, a low level on the ~KILL pin causes the EN pin to switch back to a low state, disabling the voltage regulator and powering down the system. The equation for the external capacitor determining the amount of time the pushbutton must be held to turn off the system is given below [33]:

$$C_{OFFT} = 0.000156\ \mu F/ms\ \times (t_{OFFT} - 1\ ms)$$

The TPS73601 is an adjustable voltage regulator capable of sourcing up to 400 mA of current. The equation for determining the values of the external resistor network for a given regulated voltage is given as [34]:

$$V_{OUT} = \frac{R_1 + R_2}{R_2} \times 1.204$$

The resistance R_1 is connected between the output voltage and the regulator's feedback (FB) pin, while the resistance R_2 is connected from the FB pin to ground. The reason for not simply using a 3.3V regulator was to allow the board to potentially supply other voltages for different contexts besides the Brainboard R1 design.

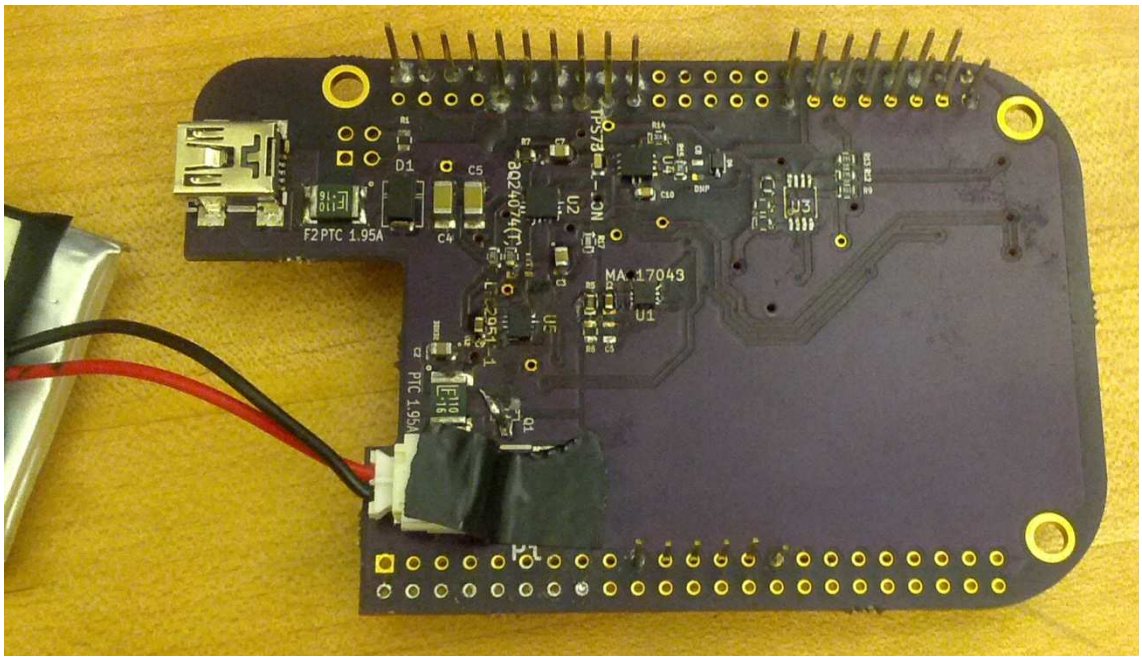

Figure 4: Battery management expansion board

Design Differentiation

Although the BBB form factor is significantly smaller than most EEG amplifiers, it still took up more space than necessary when the Brainboard was acting in a standalone capacity. In order to miniaturize the design even further, the Brainboard was differentiated into two separate versions: Brainboard R2, which was a pure BBB cape with no on-board microcontroller or Bluetooth radio, instead relying on the BBB and a Bluetooth dongle for these functions; and Brainboard LW (Lite-Wireless), which was approximately 2/3 the size of the original but could no longer plug directly onto the BBB. Since the lab's work had become more focused at this point on developing the smallest possible device, the remaining effort in this thesis focused on the Brainboard LW. Validation of the Brainboard R2 will be left for future work.

Final Design: Brainboard LW

The original BBB cape form factor was modified to take up less space. Its original 3.4” length was reduced to 2.4”, and both the notch for the Ethernet jack and the side headers were removed to allow more space for components. More components were also placed on the bottom side of the PCB.

Since there was more room on the board now, battery charging circuitry originally included on the battery adapter board was incorporated into LW. The pushbutton controller and its associated power button were replaced with a slide switch, and the fuel gauge replaced with a comparator (Linear Technology LTC1998), to simplify the implementation and reduce component count. The LTC1998 is specifically designed for low-battery detection on lithium-ion batteries and includes an on-chip reference voltage. It uses an external resistor network to set threshold voltage and hysteresis as given below [35]:

$$R_{TOTAL} = R_1 + R_2 + R_3 = \frac{4.2V}{I_R}$$

$$R_1 = R_{TOTAL}\left(\frac{5V}{V_{BATT.Th} + V_{HYST}} - 1\right)$$

$$R_2 = R_{TOTAL}\left(\frac{5V}{V_{BATT.Th}} - 1\right) - R_1$$

$$R_3 = R_{TOTAL} - R_1 - R_2$$

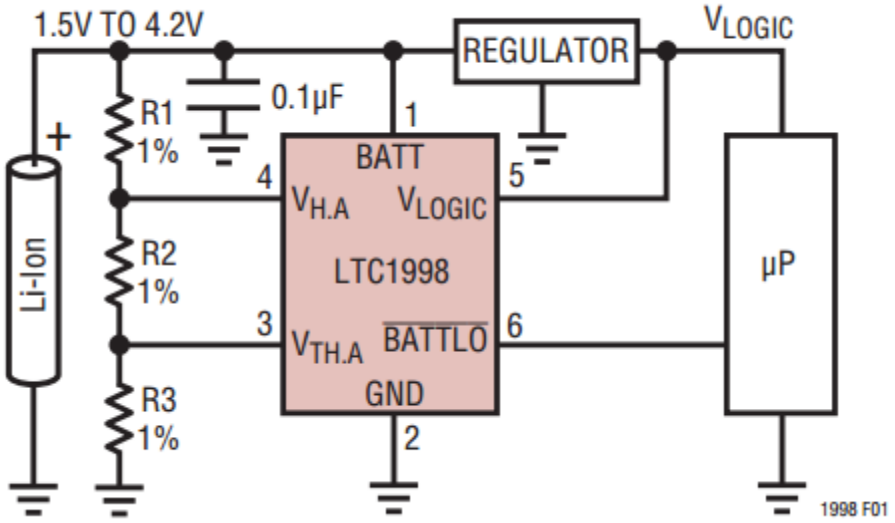

Figure 5: LTC1998 configured as low battery threshold detection with hysteresis

The network was designed such that the comparator had a threshold $V_{BATT.Th}$ of 3.1V with hysteresis V_{HYST} of 100mV, giving an upper (rising) trigger level of 3.2V and a lower (falling) trigger of 3.0V. The maximum allowable resistor current I_R (which drains the battery) was selected as 1 µA. Tripping the comparator causes its ~BATTLO pin to sink current from an LED, providing a visual indication of the low battery status. At this point the 3.3V regulator will already be sagging; however, all on-board devices support operation down to 1.8V except for the RN-42. The 3.0V trigger provides adequate time to plug in the device before battery voltage falls below the 3.0V minimum recommended level for the RN-42 power supply. The ~BATTLO signal was also connected to an external interrupt pin on the UC3L, providing the possibility of a controlled power-down procedure or a message to the host computer indicating a low battery (however, this was not implemented in firmware as of this writing).

One minor design change was changing the MPU-6050's INT pin to an actual interrupt-capable pin on the UC3L. Although not necessary for the application at hand, it might prove useful in the future to rewrite the firmware such that the inertial measurements can be taken independently from the EEG measurements (i.e., with the ADS1299 powered down or otherwise not sampling).

This design necessitated double-sided reflow, which brought up concerns about already-soldered parts falling off the board during the second pass, and I was prepared to do repairs by hand after the reflow process was complete. However, the solder surface tension was strong enough that these worries proved unfounded.

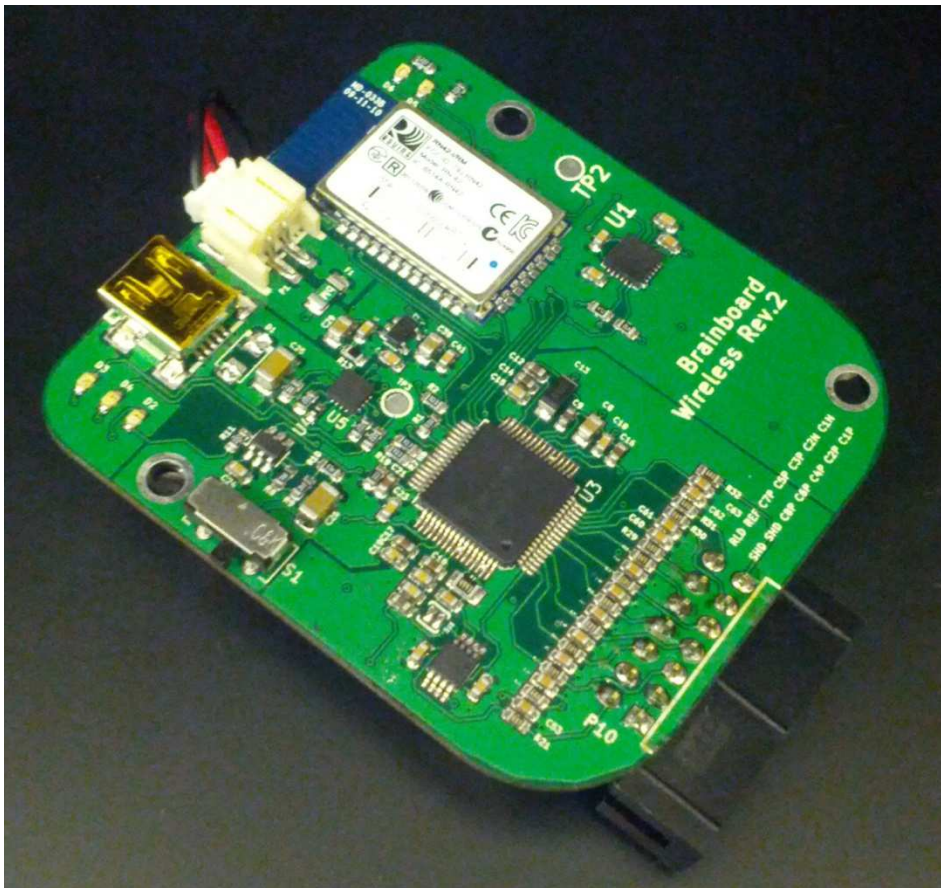

Figure 6: Brainboard LW

Results and Discussion

Signal Quality

The 0.1” pin socket electrode input to the Brainboard LW was broken out to 1.5 mm touch-proof connectors for compatibility with the lab’s electrodes. The electrodes used for signal quality comparison with a professional amplifier were actiCAP active electrodes (Brain Products GmbH, Munich, Germany), chosen to minimize potential signal degradation effects due to electrode problems. Electrodes were placed onto the subject’s scalp at positions Fz, Cz, Pz, Oz, C3, C4, and P3; however, inputs were recorded simply as channels 1-7 and their actual scalp locations were not tracked for

subsequent data analysis, since the only analysis being done was on differential signal quality between the two amplifiers.

EEG data were collected simultaneously with both the Brainboard LW and a professional DC-coupled amplifier, the V-Amp 16 (Brain Products GmbH, Munich, Germany) using a set of compatible signal splitters for the touch-proof connectors. The V-Amp was connected via USB to a laptop running BCI2VR, while the Brainboard was wirelessly connected to a separate desktop computer, also running BCI2VR. Due to data collection problems with the V-Amp 16, only channels 3-6 were obtainable; the remaining channels were inexplicably corrupted. The subject was instructed to relax, blink his eyes, and close his eyes, so as to present eye movement artifacts and alpha rhythm for comparison.

After collection, data were post-processed in MATLAB. The two signals, although simultaneously recorded, were time-shifted relative to one another since the “record” button could not be pressed simultaneously on both host PCs. This time shift was empirically determined to be 31.2 ms and was corrected. The spectrum up to 100 Hz (Welch’s modified periodogram, 600-point FFT with 600-sample windows and 50% window overlap) was calculated for both records and compared. Next the mean value was subtracted from each record to eliminate the effect of electrode bias and inherent amplifier offset, which is expected to vary between any two amplifiers and electrode setups. RMS error between the V-Amp and the Brainboard data was then calculated, both with and without a 60-Hz notch filter (8^{th}-order Butterworth, Q = 10). RMS errors for each channel in the time and frequency domains are shown in Table 3. The quantified level of 60-Hz noise pickup is given in Table 4.

The frequency response of the Brainboard LW was estimated by applying sinusoids from 0 to 300 Hz at 9 mV peak-to-peak, sampled at 1000 Hz, and recording the attenuation at the output. Output amplitude was converted to decibels referenced to the 9 mV input. The plot shows a reasonably flat frequency response out to 50 Hz, with a -3 dB point at approximately 153 Hz.

Board-level noise was measured by shorting the input pins together and measuring for 10 seconds. From these data, RMS level was calculated, and then this was converted to a peak-to-peak value using a conversion constant of 6.6 as given in the ADS1299 datasheet. Input-referred noise levels were measured at a gain of 24, the gain at which all other tests besides frequency response were performed. Mean V_{rms} and V_{pp} for the Brainboard were 0.409 µV and 2.67 µV, respectively. These are higher than the V-Amp's reported specs of less than 1 µVpp noise [36], but not egregiously so. The measured noise is likely dependent on ambient conditions, as well, and these were not optimal in the lab, given the large number of active computers and other RF radiators. The noise spectrum is shown below. A close-up of the 0-65 Hz range, which is the range given in the ADS1299 datasheet for specified performance, is also shown. The response is almost flat over this range, indicating acceptably low distortion of acquired EEG.

Channel	Unfiltered time-domain RMSE (µV)	Filtered time-domain RMSE (µV)	Frequency-domain RMSE (dB)
3	23.5	23.2	2.32e-11
4	12.6	10.4	2.32e-11
5	20.3	19.5	1.35e-11
6	26.7	25.9	8.68e-11

The Brainboard LW has identical performance to the V-Amp up to around 70 Hz, at which point its attenuation drops off more shallowly. The V-Amp likely has sharper analog filtering than the Brainboard, which only uses first-order anti-aliasing filters at 42 kHz. Mains pickup is comparable between the two devices. Noise performance might be improved through design of an appropriate metal enclosure for the analog portion of the device. It is unclear what caused the anomalously low 60-Hz power on the V-Amp's channel 3. It's possible that the other values are in fact anomalously high and the electrodes were poorly plugged into the amplifier, or that noise coupled between the Brainboard and the V-Amp due to the simultaneous recording method.

The Brainboard's noise is shown to have an approximately Gaussian distribution, confirming the approximately constant power spectral density observed in the spectra above.

Power Consumption

Current consumption was tested in different device states using a handheld DMM placed in series with the battery through an intermediate plug and jack. This information is shown in Results below. The maximum power consumption of 85 mA took place, as expected, during continuous data streaming at 250 Hz. This figure would theoretically allow just under 12 hours of run time on a 1000 mAh battery such as the one employed for testing; however, this was not verified empirically due to the impracticality of observing the device for such a long period of time. A 12-hour continuous run time should far exceed what is needed for the lab's experiments, but it isn't quite sufficient for, say, an all-day-wear prosthetic. Such an application would necessitate on-board processing of some kind, whether data analysis or compression, in order to reduce the radio's transmission duty cycle.

Reducing the power consumption of the device is possible on multiple levels due to the scalable operation of different components on the board. For example, the MPU-6050 can power-off its gyroscope, its accelerometer, or both (although the accelerometer consumes negligible power); the RN-42 may duty cycle its radio operation according to the Bluetooth SNIFF protocol [37]; the ADS1299 can power-down some of its channels or go into standby mode; the UC3L may go into a number of software-controlled sleep modes. The applicability of these different power consumption reduction methods depends on how the Brainboard is to be used: for example, a pure

data-streaming mode like what was evaluated in this thesis would likely require all of the devices to be operating at full capacity except perhaps for the MPU-6050. Radio power consumption could be reduced by implementing a compression algorithm, although at the expense of some extra power consumed by the MCU. The MCU might also be operated at a lower clock speed, although this might affect its ability to efficiently perform the compression algorithm. One final suggestion is to keep the Bluetooth radio in low-power sleep mode, buffer some of the data, and then send it in a burst transmission over the Bluetooth link before returning to sleep.

As an investigation into the feasibility of this latter option, let us consider the following. The RN-42 has two sleep modes: standard sleep, at which the module consumes about 2 mA, and deep sleep, at which it consumes 300 µA. The module consumes about 30 mA when connected and 45 mA when transmitting, so this is a significant savings. There is a catch to the deep sleep, however: it has a 5 ms worst-case wakeup time [38], corresponding to 1.25 sample periods at 250 Hz. The RN-42 then stays awake for exactly 1 second of inactivity before returning to deep sleep, meaning that the microcontroller must buffer at least 1 second of data, or the module will never return to sleep! Moreover, the RN-42 isn't even asleep during this 1 second, limiting our power savings to 15 mA. Since 1 second of 8-channel sampling corresponds to 8000 bytes of 32-bit-encoded 24-bit data, already half the RAM on the device, we will have to settle for the higher-power sleep mode.

Each packet of sent data consists of 18 non-EEG bytes, along with 24 EEG bytes per sample (the current implementation, with no accumulation of samples in the buffer, thus has 42 bytes per packet). Assuming no overhead and 115,200 bit/s transmission

rate to the RN-42, each packet will take 1.25 ms, plus 1.67 ms/sample, to offload. If only one sample is sent, this will take 2.92 ms, which is already almost as long as the sample period. The current consumption here is:

$$\frac{(30\ \text{mA} \times 1.08\ \text{ms}) + (45\ \text{mA}\ \times\ 2.92\ \text{ms})}{4\ \text{ms}} = 40.95\ \text{mA}$$

Now let us presume that we keep the RN-42 asleep for 124 ms while buffering 31 samples, initiate wakeup and wait another 5 ms (buffering another sample in the process), and then send data for (1.25 + 1.67 x 32 = 54.69 ms). This gives an average current of

$$\frac{(2\ \text{mA} \times 124\ \text{ms}) + (45\ \text{mA}\ \times\ 59.69\ \text{ms})}{183.69\ \text{ms}} = 14.75\ \text{mA},$$

a 64% reduction in power.

Some common device states with their corresponding current draw from the battery are shown in Table 5. Note that there is actually very little difference in power draw between enabling and disabling the RN-42's LED drivers. This is due to the relatively large resistors placed in series with the LEDs (2.2kΩ). The driving voltage is 3.3V, resulting in only 1.5 mA of LED current.

ADS1299 Status	# Active Channels	RN-42 Status	RN-42 LEDs	Gyro	I (mA)
Power-down	N/A	Reset	N/A	Off	30.1
Standby	N/A	Idle	Disabled	Off	36.8
Normal, bias on	1	TX @ 250 Hz	Disabled	Off	71
Normal, bias on	8	TX @ 250 Hz	Disabled	Off	82
Normal, bias on	8	TX @ 250 Hz	Disabled	On	85
Normal, bias on	8	Idle	Enabled	On	56
Normal, bias on	8	TX @ 250 Hz	Enabled	On	86.5

Table 5: List of common device states and corresponding current consumption

Cost

The final cost of a single Brainboard LW board was $135.01 for components, $17 for the bare PCB, $10 for a stencil, and $12.95 for 50 grams of solder paste. Note that this doesn't include assembly costs (I assembled it myself) or the cost of an enclosure, or electrode costs. These would add to the price of the final product if it were sold. The component BOM is given below:

Item Value	Quantity	Manufacturer	PN	Distributor	Ext Price
Capacitor 1nF	1	Kemet	C0603C102K3RACTU	DigiKey	$ 0.10
Capacitor 2.2nF	1	Kemet	C0603C222K5RACTU	DigiKey	$ 0.10

Table 6: Component bill of materials

Conclusion and Future Work

The Brainboard is a functional EEG and acceleration/rotation acquisition board with the advantage over commercial devices of being reprogrammable by anyone with a free copy of Atmel Studio and an AVR Dragon ($49 directly from Atmel). Its components, other than the microcontroller, are all popular among hobbyists and the open-source hardware community and thus have a wide range of free application code and use cases available on the Internet. Atmel provides free code libraries in the form of the ASF, which eases use of the Brainboard's microcontroller. However, it has a way to go before it can achieve the ease of use and low cost needed to make it a widely adopted device.

Outside of electronics development, one simple future project is a case for the PCB. This could be manufactured quite simply using a 3D printer or laser cutter, both of which are available in relatively inexpensive consumer forms.

Inclusion of a USB bootloader would vastly improve the ease of programming, since no awkward cable would need to be plugged into the JTAG port, and no AVR Dragon would need to be purchased. However, more importantly, I would recommend that future development based on the Brainboard design begin with porting to a different microcontroller. The UC3L, while capable of supporting the application for which it was used, is underpowered in many respects, such as RAM and available libraries, not to mention user support. Adoption of a microcontroller with Arduino IDE compatibility, or a

non-Arduino device with a large user support base such as the STM32 series, would be a huge step in the right direction. Since most of the Arduino-compatible platforms are 8-bit devices with drastically reduced memory capacity and clock speed versus the UC3L, the latter option would be preferable (although the recently announced Arduino Zero, which introduces support for an ARM Cortex-M0+ MCU running at up to 48 MHz and having 32 KB of SRAM, would be an excellent candidate once it is released [39]. A Cortex-M4 device, which has powerful DSP specializations and inherent support for ARM's own core-optimized DSP library, would be an even more attractive option; the Teensy 3.1 is such a device, and it has support for Arduino-style programming and almost all Arduino libraries, although it is a full PCB system rather than a chip and requires a proprietary bootloader [40]. A possible option would be redesigning the Brainboard as a Teensy expansion board. The Tiva microcontrollers from Texas Instruments also have a strong hobbyist following thanks to TI's low-cost ($12.99) Launchpad development boards, and they can be programmed in an Arduino-like IDE called Energia [41].

Further pursuing of the Beaglebone Black integration is another logical step, since this would drastically improve the Brainboard's BCI processing capability and ease of software development. The first step should be software development so that the already-existing R1 can interface with the BBB; this could come in the form of a modification of BCI2000 or Open-Ephys's GUI. The second step would be refining the R1 into a more streamlined, lower-cost product. This step is already underway with the design of the Brainboard R2, a stripped-down board meant to operate solely in conjunction with the BBB and a Bluetooth dongle. Ultimately, given the fully open-

source nature of the BBB, I would like to develop a completely customized board incorporating components from the Brainboard and BBB. This would also allow bypassing the relative difficulty of running the BBB off of battery power, since unused parts of that board could be removed in this custom design (e.g. Ethernet, USB host, HDMI).

I envision the Brainboard eventually as a multi-embodiment ecosystem of devices with varying capabilities, ranging from simple data streaming to complex BCI processing. The simplest version could work with a basic 8-bit Arduino-compatible MCU, while intermediate versions might have a Cortex-M4 device capable of mid-level processing, and the most advanced ones would have a full-featured microprocessor like the Cortex-A8 on the BBB. The cost to the user of these devices could be minimized by making them interchangeable with a single sensor board containing the ADS1299 and MPU-6050, or whatever their successors might be. These would all be in a form factor small enough to allow them to be worn on the body.

The final roadblock toward mainstreaming EEG-based BCI systems is the inconvenience of traditional wet electrodes. Dry electrodes that can operate through hair remain expensive, and it is unclear whether or not they fully meet the wet gold standard. This would be the final direction to take: research into a user-friendly, easily donned and doffed electrode setup. Once this goal is reached, I believe EEG BCI will have finally entered into its own.

Unfortunately in some respects and fortunately in others, this project was begun on the eve of a flurry of activity regarding open-source neurophysiology and BCI platforms. Such recent projects as OpenBCI and Open Ephys—the former of which

even uses the same ADS1299 chip and acts as an Arduino expansion board—have a time-to-market and manpower advantage over Brainboard, but the success of Brainboard is less important than the community interest it was intended to build. The goal is commonplace, affordable brain-computer interfaces, and I believe this goal is not too far away.

Vita

Graham Kelly was born on July 5, 1990 in Greensboro, NC, USA. He received his Bachelor of Science degree in Biomedical Engineering from Virginia Commonwealth University in May of 2011. Afterward, he began working as a lab technician in VCU's Artificial Heart Lab under Dr. Miller and Charles Taylor, where his work included electronic control systems prototyping, mechanical component design and fabrication, ECG signal processing, and image processing of fluid flow. It was in the Heart Lab that Graham was first exposed to Maker culture and the DIY ethos. He joined VCU's Master of Science program in Biomedical Engineering under Dr. Ou Bai to pursue his longtime interest in the brain and neural engineering. His research interests include brain-computer interfaces for advanced prosthetics, wearable electronics, and the application of nanosensors to real-time minimally invasive brain activity recording. He plans to enter the medical device industry before returning to school to get his Ph.D.

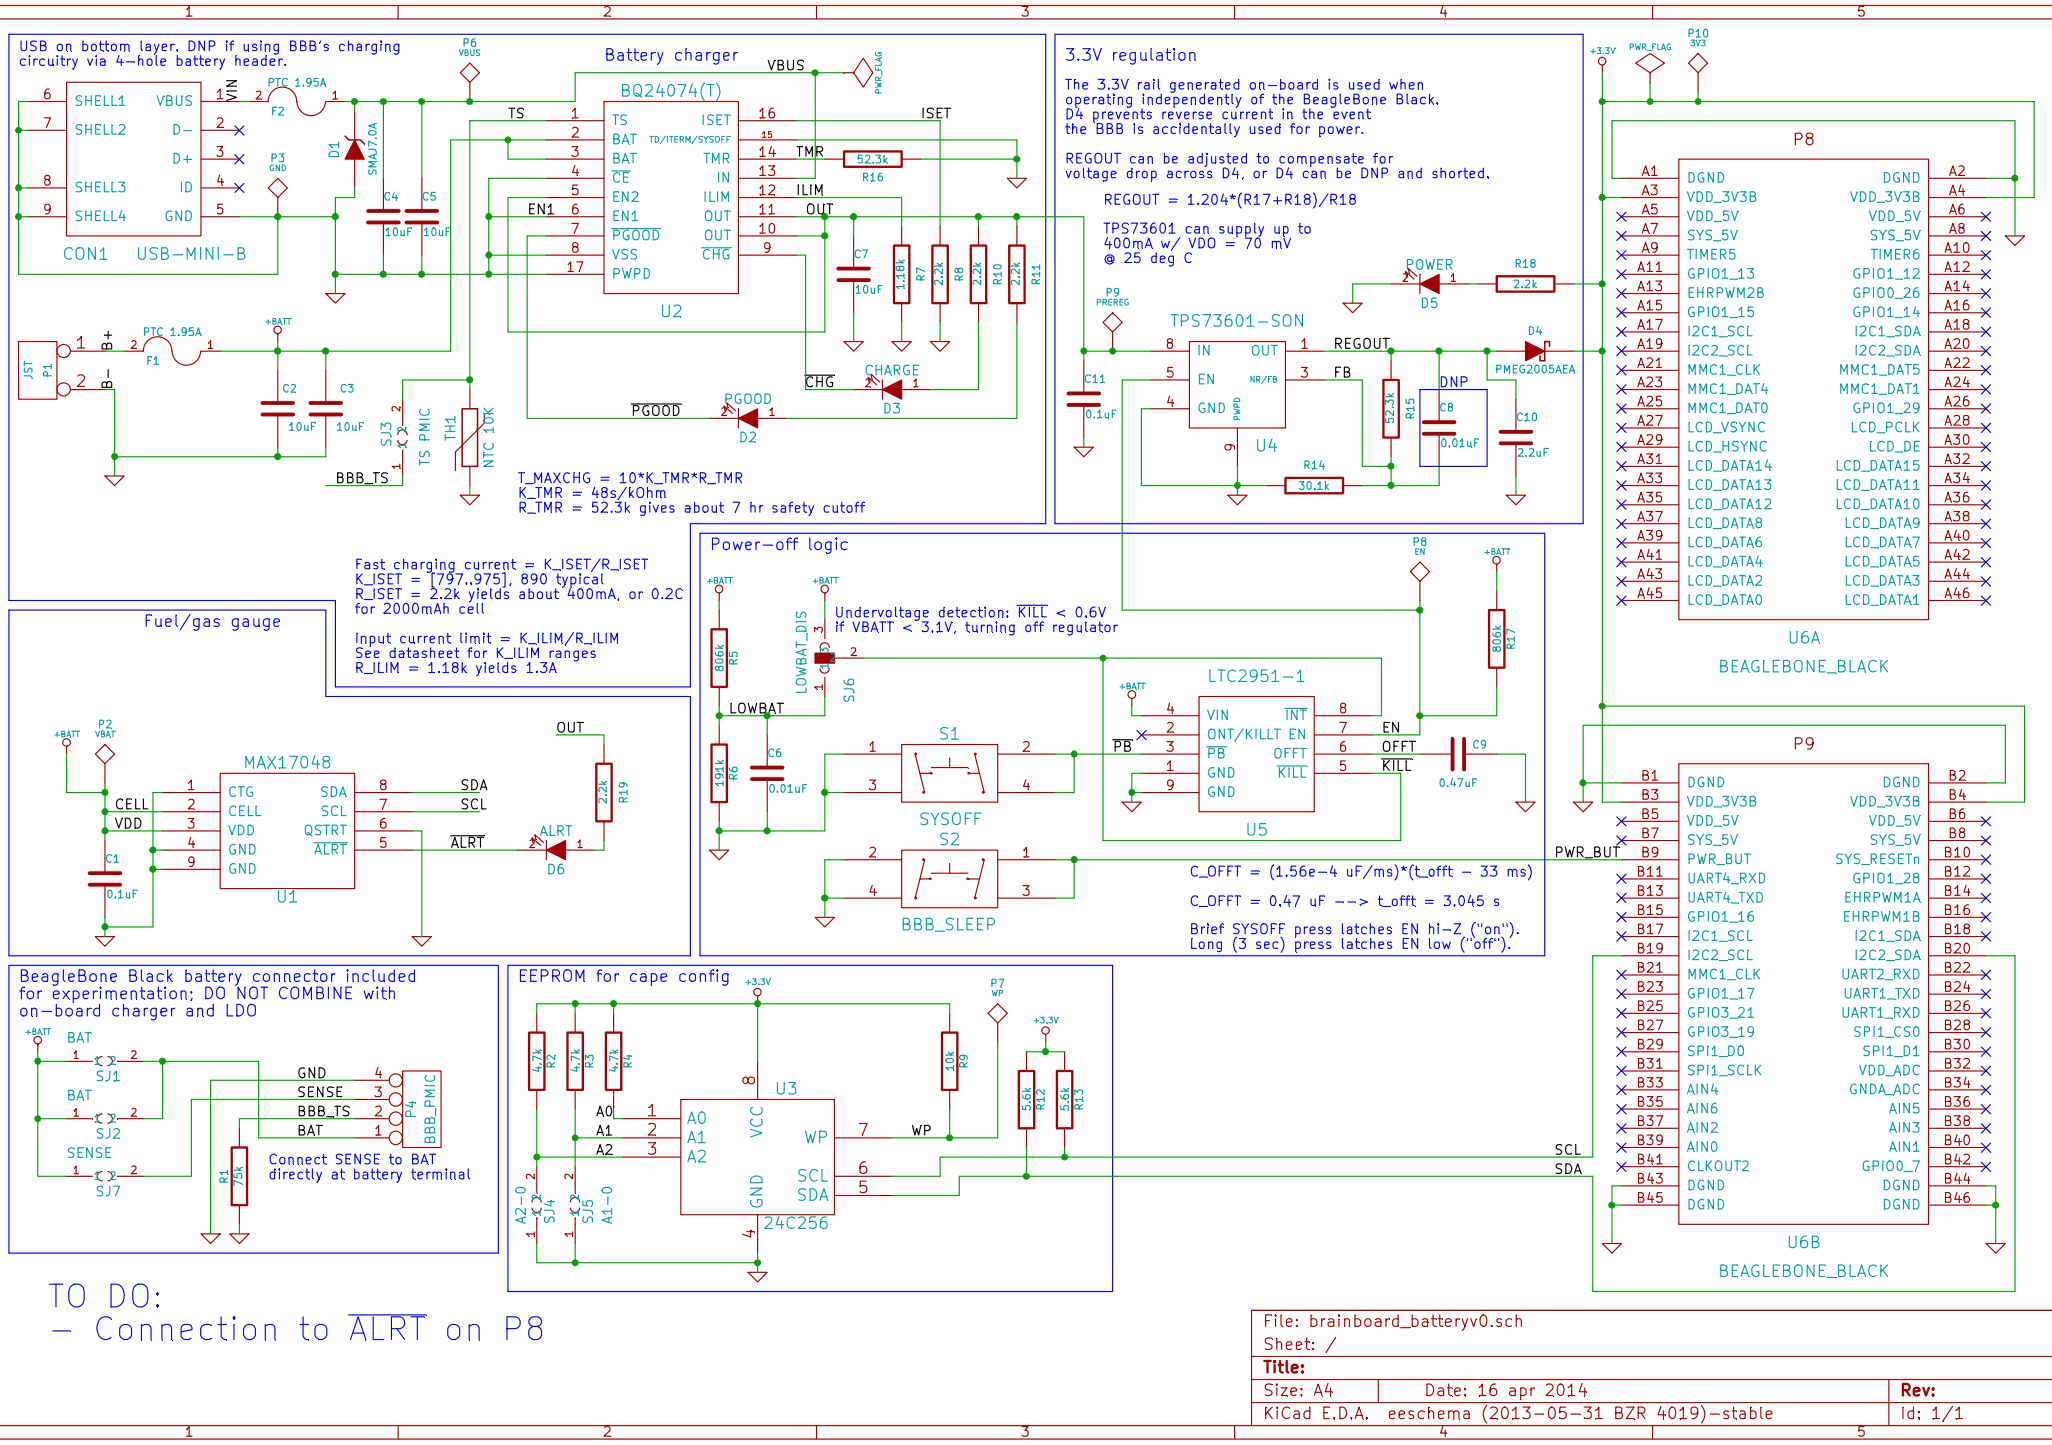
Battery Board



USB on bottom layer. DNP if using BBB's charging circuitry via 4-hole battery header.
CON1 USB-MINI-B
Battery charger
BQ24074(T)
U2
T_MAXCHG = 10*K_TMR*R_TMR
K_TMR = 48s/kOhm
R_TMR = 52.3k gives about 7 hr safety cutoff
Fast charging current = K_ISET/R_ISET
K_ISET = [797..975], 890 typical
R_ISET = 2.2k yields about 400mA, or 0.2C for 2000mAh cell
Input current limit = K_ILIM/R_ILIM
See datasheet for K_ILIM ranges
R_ILIM = 1.18k yields 1.3A
3.3V regulation
The 3.3V rail generated on-board is used when operating independently of the BeagleBone Black. D4 prevents reverse current in the event the BBB is accidentally used for power.
REGOUT can be adjusted to compensate for voltage drop across D4, or D4 can be DNP and shorted.
REGOUT = 1.204*(R17+R18)/R18
TPS73601 can supply up to 400mA w/ VDO = 70 mV @ 25 deg C
TPS73601-SON
U4
Fuel/gas gauge
MAX17048
U1
Power-off logic
Undervoltage detection: KILL < 0.6V if VBATT < 3.1V, turning off regulator
LTC2951-1
U5
SYSOFF
BBB_SLEEP
C_OFFT = (1.56e-4 uF/ms)*(t_offt - 33 ms)
C_OFFT = 0.47 uF --> t_offt = 3.045 s
Brief SYSOFF press latches EN hi-Z ("on"). Long (3 sec) press latches EN low ("off").
BeagleBone Black battery connector included for experimentation; DO NOT COMBINE with on-board charger and LDO
Connect SENSE to BAT directly at battery terminal
EEPROM for cape config
24C256
U3
P8
U6A
BEAGLEBONE_BLACK
P9
U6B
BEAGLEBONE_BLACK
TO DO:
- Connection to ALRT on P8

 *****************************************************************************************************************/

/**
 *  \brief Default data rate from the ADS1299.
 *
 *  To monitor electrode impedance continuously, an AC current is pulsed through each electrode and the corresponding
 *  voltage perturbation observed in the measured signal. This signal will not be easily separable from the EEG if it
 *  is within the typical 0-100 Hz EEG bandwidth; since the fastest possible AC excitation rate the ADS1299 can
```

```
 *  generate is (data rate)/4, the lowest recommended data rate that allows continuous impedance monitoring is 1000 Hz.
 *  Using a 500 Hz data rate will generate an AC excitation at 125 Hz, which is dangerously close to, if not in,
 *  the EEG band.
 */
